1 Individual Contributions

The distribution of our work was mainly influenced by the fact that Marco had to join a refresher course at the Swiss Army in April. Therefore, his effort was mostly done during the first part of our project. He started by searching the internet for reliable airplane plans to get to know the seat configuration and afterwards set up a Matlab scenario of the whole plane. After several discussions with the group, on how to proceed, he implemented the first model and set the base of our project. During Marco's absence, Laurent and Dominik took over Marco's work and continued the project. As the first model was quite limited in its flexibility, we decided to implement another model, namely the one with static field. Dominik changed the existing airplane model according to the new requirements. He was engaged in searching algorithms to compute a static field of the plane and afterwards implemented one of them in *Matlab*. Laurent then, implemented the new model functions in *Matlab* and changed the old simulation in order to make it work with the static field. In the phase of optimization we collaborated a lot and helped each other. In addition we discussed the results and how to interpret them. Having done the main part of the project, we started writing our report. The individual responsibility on writing the different parts is listed below. Laurent then implemented our writing in LaTeX form.

2 Introduction and Motivations

The airplane-security is an important issue on aircraft engineering. There are specific laws about how fast an evacuation of an airplane has to occur. Those laws have to be observed; otherwise, the airplane does not get the permission to fly. Additionally, the new airplanes are bigger, carrying more and more people. Therefore, evacuation scenarios are growing in their complexity and it is difficult to estimate, how the evacuation takes place. This simulation should help the engineer to get a better understanding of evacuation situations in airplanes. With certain assumptions taken, it shows the process of evacuation, plus how different parameters influence the evacuation time.

The following report is part of the lecture "Modelling and Simulating Social Systems in *MATLAB*" at ETH Zurich. The course involves different aspects of modelling and simulating social systems, as well as implementing them in a computational environment using Mathworks *MATLAB*.

3 Description of the Model

3.1 General description

The physical appearance of the model is given by the dimensions and seat configurations of the Airbus A380. However, every airline has the opportunity to design its own seat configuration. Thus, it is difficult to find any exact plans of the interior. After some research on the web, we decided to take the interior design according to figure 1 on page 9.

The Airbus A380 has got 2 different decks: the upper deck and the lower deck. They differ in the interior design and the seat configuration, as well as in the possible number of passengers. Therefore, the two decks are treated separately. The most important difference between the two decks is the number of exits. The upper deck has got 8 emergency exits, whereas the lower deck has got 10 of which. In order to obtain a convenient model, there were some assumptions to be taken. These assumptions are listed below. Their purpose is to minimize the complexity of the model, since a model is always a simplification of the reality.

- People take the nearest possible exit: We assume that in case of emergency, people always choose the nearest exit location. In reality, the choice of the exit is much more complex, since it is also influenced by factors such as crowd behaviour, panic, signalisation, etc.
- Airplane model simplified: Our airplane is extremely simplified, as we are limited by the methods of implementation. Therefore, all of our passenger seats commensurate. Also, the space between the corridors is not exact. The width of the lower and upper decks is different, the seats of the crew are neglected, as well as the toilets and structural elements.
- People act with a certain probability: As an assumption, we suggest that people act with a defined probability. Statistically, this probability can be interpreted as various factors, such as intelligence, age, or the passenger's disorientation.
- Upper and lower deck evacuate separately: This means, that there is no connection between the two decks. People can't use the stairs.
- People start evacuating immediately: The passengers do not hesitate or try to organize themselves when the case of emergency happens. They all start the evacuation at the same time and without individual delay.
- All people behave the same way: Our models treat every passenger the same way. They don not differ between age, speed, size, or enthusiasm of the individual. Thus, it can be seen as a statistical average of all people.

AIRBUS 380

Figure 1: Airbus A380 interior design reference

• People are not climbing over seats: We assume that the passengers are not affected by panic behavior, so they do not climb over seats, but behave respectably. Also, it is quicker to run through the aisle instead of climbing over some seats. Consequently, the assumption is quite rational.

As we were not fully satisfied with the first model, we decided to implement another one. The two models differ slightly, so they are treated separately. Both models use the so-called von Neumann neighbourhood type. This means, that the four cells orthogonally surrounding a central cell are defined as a neighbour of the central cell.

Figure 2: von Neumann neighbourhood: the grey cells are the neighbours of the central cell marked with red

3.2 Model 1

Figure 3: Seat configuration, Model 1

<u>Behavior</u>: At the beginning of every simulation step, a random passenger is chosen. All the action occurs on that specific passenger until the next simulation step chooses another passenger. At first, the program detects the passenger's location. Secondly, the passenger's minimal distance to the nearest exit is being calculated. Afterwards, the passenger moves, based on a specific algorithm (see implementation), and updates his matrix field, as well as the matrix fields of his surroundings. There are four different functions which lead the passenger to the nearest exit, depending whether the nearest exit is located above or below, as well as on the right or on the left side of the passenger. To include the various factors, which are mentioned earlier, the choice of the passenger's next location comprises a probability factor. Further details are provided in the implementation section.

3.3 Model 2

For this model, we had to slightly change the seat configuration. In fact, we inserted some free space between each seat row, where the passengers can move. This change was necessary for the new implementation with the static field.

Figure 4: Seat configuration, Model 2

<u>Behaviour</u>: At first, all the passengers stand up, and by doing so, switch to the free space in front of their seat. Now, they all stand on a field. Each field contains a number with the minimum distance to the nearest exit. The only thing the algorithm has to do, is to move the passenger to a field with a smaller number. Mathematically spoken, the passenger moves in the direction of the static field's gradient. This step is done with a certain probability. The probability defines whether to take the best or the worst opportunity to move. The static field is calculated in a previous step and handed over in a matrix to the main function.

Figure 5: Static field

4 Implementation

4.1 Model 1 - Implementation

After creating a model of both decks, the idea was to create a mathematical image of the model and change it with every iteration step. Due to the fact of having two decks, each function has been written according to the choice of the deck. Some functions have even been written for only one deck. There is one main-function containing several sub-functions to perform the evacuation. All functions will shortly be explained. For further information, check the source code section starting on page 37.

4.1.1 Function make_upper_level.m and make_lower_level.m

The different items such as walls, exits, free space, occupied space, free seats, and occupied seats, are only distinct by different numbers. The function to create those numbers is called *make_upper_level* respectively *make_lower_level*.

Figure 6: Numerical implementation of the initial situation

The numbers in figure 6 on page 13 are called the coordinate's state.

4.1.2 Function $upper_level_sketch.m$ and $lower_level_sketch.m$

Every state has been given a different colour in order to visualize the different states, and to distinguish between passengers, walls, seats and so on. The functions for this step have been named *upper_level_sketch* and *lower_level_sketch*.

Figure 7: Visualization of the initial states using the level_sketch function

4.1.3 Function ploc.m

Every cell in the model has its own coordinates separated in length- and widthposition. Therefore, it is easy to determine locations and distances between two points. The general idea is, to pick a random passenger, check his location, find out its nearest exit location by calculating the distances between the passenger and all exit-locations, pick the nearest exit, and finally lead him to that exit. How the passenger is led to the nearest exit will be explained later. At first, a short inside on how the passenger's coordinates are calculated. (The coordinates of the exits are calculated analogously). Now, the exit and passenger coordinates have been calculated and can be compared.

```
1 function [passenger_location] = ploc(length_,width,passenger_number,level)
2 % this function calculates the passenger's coordinates
3 passenger_location = ones(passenger_number,2); % default
4 k=1;l=1;
5 for i = 1:length_ % iterate over the whole length
6 for j = 1:width % iterate over the whole width
7 if level(i,j)==3 % if there is a passenger
```

```
passenger_location(k,1) = i; % safe length-coordinate
8
                passenger_location (1,2) = j; % safe width-coordinate
9
                k = k+1; % choose next passenger's length-coordinate
10
                l = l + 1;
                         \% choose next passenger's width-coordinate
11
12
           \mathbf{end}
13
         j=j+1;
14
      end
     i = i + 1;
15
  end % stop when all passenger coordinates have been stored
16
```

4.1.4 Function min_distance.m

The function *min_distance.m* measures the distance to the nearest exit of a random passenger as well as the location of his nearest exit by applying the Pythagorean Theorem: nearest line between 1 and 2 in a Cartesian coordinate system equals $\sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}$.

```
delta=1000*ones(1,2); % default
  k=1;
2
      for j = 1:length_(exit_location) % Pythagoras for all exits
3
           delta(k,1) = abs(passenger_location(1,1) - exit_location(j,1));
4
           delta(k,2) = abs(passenger_location(1,2) - exit_location(j,2));
5
           deltanorm(k) = sqrt(delta(k,1)^2 + delta(k,2)^2);
6
7
           j = j + 1;
8
           k=k+1;
      end
9
      [min_dist, index] = min(deltanorm); % choose minimum
10
      % calculate nearest exit coordinates
11
      nearest_exit_location(1,1) = exit_location(index,1);
12
      nearest_exit_location(1,2) = exit_location(index,2);
13
```

4.1.5 Function passenger_move.m

Knowing the target location and the starting location, the passenger is led to the exit with the following function, which depends on several conditions and differs in some aspects considering diverse starting situations: function *passenger_move.m*

- 1. passenger is stuck on the left side
- 2. passenger is stuck on the right side
- 3. passenger is on free space and the nearest exit location is below
- 4. passenger is on free space and the nearest exit location is above
- 5. passenger is on a seat in the front row
- 6. passenger is on a seat and the nearest exit location is on his right

- 7. passenger is on a seat and the nearest exit location is on his left
- 8. passenger is on the same height as the exit, exit is on his right
- 9. passenger is on the same height as the exit, exit is on his left

The next step to take in each situation is listed in the table 1 on page 16

Situation: Passenger is (on)	Priority 1	Priority 2	Priority 3
Stuck on the left side	twice right	-	-
Stuck on the right side	twice left	-	-
Free space / exit is below	Down	Left / right	stay
Free space / exit is above	Up	Left / right	stay
Front seat	Up	-	-
Seat / exit is right	50% right	50% left	stay
Seat / exit is left	50% left	50% right	stay
Same height as exit , exit is left	Left	-	-
Same height as exit , exit is right	Right	-	-
	1		

Table 1: Next step algorithm of the function *passenger_move* (for details check source code)

Of course, the passenger can only move, if the space he wants to go to is free. To check the availability of the next location, its state is always being checked. Also, the "old" passenger location's state has to be updated. However, that is not done by this function but with the evacuation function that will be explained later on.

To check the states of the passenger's neighbour cells, and add probabilities, the following approach has been used:

```
function [new_location] = passenger_move(passenger_location ,...
           nearest_exit_location , level )
2
3
  \% This function calculates the next step for a passenger who wants
4
  % to reach the nearest exit at all costs!
5
6
  % all possible neighbour cells a passenger can move to in one step
7
  % meaning: [up; right; down; left; stay]
  neighbour=[-1 \ 0; \ 0 \ 1; \ 1 \ 0; \ 0 \ -1; \ 0 \ 0];
9
10
11 for i = 1: length (neighbour)
  new_location(i,:) = passenger_location+neighbour(i,:);
12
   % safe all possible new_locations of the passenger
13
14 end
15
16 prob = rand; % variable to add probabilities
```

4.1.6 Function evacuatioin.m

 $1 \ \% \ level = [1,2] \ visual = [0,1] \ movie = [0,1] \ meaning: \ 0 = no \ 1 = yes$

All preceding functions are required to safely lead one random passenger one step nearer to his nearest exit. The main-function *evacuatioin.m* ensures that all passengers eventually reach the exit. Details are listed in the source code section. However, to shortly introduce the function, some main tasks have to be mentioned:

- choosing: the level / visualization (on/off) / record movie (on/off)
- measure the evacuation-time
- remove passenger that has reached the exit
- updating the new states of all fields
- invoke all preceding functions in the right order

Figure 8: Screenshot of an emergency evacuation simulation

4.2 Model 2 - General description

Model 2 was implemented in *Matlab*. The main function is called $evac_V5.m$ as shown on page 47. It takes two input parameters to decide whether the simulation has to visualized and a movie is to be recorded or not. See table 2 on page 18 for the exact values for each case. The function calls several sub functions, called in the *SIMULATION* part of the program.

Movie	Visualize: yes	Visualize: no
Yes	$evac_V5(1,1)$	$evac_V5(0,1)$
No	$evac_V5(1,0)$	$evac_V5(0,0)$

Table 2: Input parameters for the function $evac_V5.m$

In the *POST PROCESSING* section, time measurement settings are initialized and allocated. The variable *level* was introduced to facilitate a two level simulation in the future. The only requirement would be the mapping of the first, respectively second floor and running the program for each level. The SIMULATION section is the heart of the program. First of all the function *initialize* m is called, which builds the map of the cabin according to the static field. The static field is created externally and needs to be in the same folder as the main program. In the next step, the position of each passenger and exit is evaluated. If visualization is required, the function *field_upper_level_sketch.m* draws the frame of the actual situation in the plane. Finally, the emergency situation starts and the passengers get up with the function paxGetUp.m. The for-loop starting at line 65 of prgram 8 calculates the evolution of the simulation for each time step. In the POST PROCESSING section one can choose how many passengers move per time step. A check is required to know whether there are still enough passengers in the plane or not, which is done with a simple *if* condition. Should there be less passengers to move in the plane, the number of passengers moving per time step is set to the number of agents remaining in the cabin. The matrix *paxLocations* contains the x and y coordinates of each passenger. The arrangement is purely random. With *paxMove.m* the passenger with coordinate x and y is moved. More details of the function will follow later in the text. After moving the chosen number of agents, the number of remaining passengers, their location and the elapsed time has to be computed. If required, a new frame will be saved and the loop repeated until the plane is empty or the maximal simulation time has been reached.

4.3 Model 2 - Function descriptions

Subsequently, the different functions are extensively and sequentially explained according to the main program.

4.3.1 Function initialize.m

In this function, the cabin is built according to the geometric information in the static field (see listing 10 on page 50). To build the interior of the airplane the function *field_make_upper_level.m* is called. It takes the length and width of the plane an positions the seats with passengers, walls and exits. Empty seats could be set as well. In a double *for* loop the the number of passengers and exits are being count. The function returns the number of passengers and exits, length and width of the cabin and the matrix with the cabin information. This matrix contains the location of seats, passengers, walls and exits.

4.3.2 Function paxLoc.m

Listing 11 on page 51 shows the function paxLoc.m which returns a matrix with the x and y coordinates of each passenger and exit. In the matrix containing the cabin information, passengers are described with a 3 and exits with a 4. This function simply returns the x and y coordinate of each passenger in a random order. The *Matlab* function randperm(n) returns a random permutation of the integers 1:n. These values are required to copy the data content of the position matrix into a new randomly sorted matrix, which is returned.

4.3.3 Function paxGetUp.m

This function, to be found in listing 13 on page 52, replaces each value in front of a seat (with seated passenger) with a passenger (3) and replaces its original place in the cabin information matrix by a seat (5). It returns the updated cabin information matrix and a count value, which can be used for double check purposes while debugging the program.

4.3.4 Function *paxMove.m*

Listing 9 on page 49 shows the most important of all sub functions. In a first step, the neighbors are being defined. For an airplane evacuation, von Neumann neighbors are useful because the agents are not allowed to jump diagonally over the seats. The tmp vector is required to check later on, whether the agent is doing his best move or not. The first for loop iterates over all neighbors of the particular passenger and

remembers the value of the static field, if the cell is available. If a cell is a seat, wall or other passenger, the agent is not allowed to move to it. If the cell is good to go, the value of the static field is saved in the tmp vector. This is required to choose the best movement for each passenger. If one neighbor is an exit (4), the value of the passenger's position in the cabin information matrix is set to one (free space) and the function is left. In a second step, the probability of the best move is set. In our case it is 75%. If the probability is higher than 75% the passenger moves towards the worst direction, according to the tmp vector. If the probability is within the 75% range, the agent does its best possible move, also according to the tmp vector. The function returns the updated cabin information matrix.

4.3.5 Function field_make_upper_level.m

Listing 15 on page 53 shows the function paxLoc.m which sets the correct value according to table 3 on page 20 into the cabin information matrix and returns it.

Number in matrix		Physical meaning	Color
1	=	free space	white
2	=	wall	grey
3	=	passenger	blue
4	=	exit	red
5	=	empty seat	black

Table 3: Nomenclature in cabin information matrix

4.3.6 Function field_upper_level_sketch.m

Here, the cabin is drawn according to the geometric information in the cabin information matrix (see listing 12 on page 51). The matrix fields are colored according to the value in table 3 on page 20.

4.4 Static field

The implementation of Model 2 requires a matrix where every cell contains the shortest distance value to its nearest exit. As of now, this matrix is called static field matrix.

Figure 9 on page 21 shows, how the final result should look like. The red cells represent the exits and the black cells stand for the walls and seats. Those black cells are treated like obstacles. So, their distance value approaches infinity. To compute

Figure 9: Static field matrix, final result

the static field matrix, we used the Floyd-Warshall algorithm. It is a "graph analysis algorithm for finding shortest paths in a weighted graph" [1].

Figure 10: General path-finding problem

At first, we created a new matrix B with dimension $(l \cdot w) \times (l \cdot w)$, whereas l is the length of the airplane and w the width. This matrix is needed to save the distance between the cells (i,k) (i [1..l], k [1..w]) and all the other cells. All cell values are set to 100'000. Then, we took the l x w matrix "upper_level", which contains the plan of the airplane, and inserted each cell's neighbor information into the matrix B. Finally, we applied the Floyd-Warshall algorithm to the matrix B.

```
1
2
1
2
for k=1:(1*w)
3
4
for i=1:(1*w)
5
B(i,j)=min([B(i,j);(B(i,k)+B(k,j))]);
6
end
7
end
8
end
8
end
```

The algorithm iterates over all cells, columns and rows of the matrix B and stores the minimum distance. As a result, we got the matrix B, containing the minimal distance between each pair of cells. The matrix B is a $(l^*w) \times (l^*w)$ matrix. Therefore, we had to reduce it by choosing an exit and listing the distances to the other cells in a l^*w matrix. This process was performed with every exit, resulting a matrix C of size $l \cdot w \cdot (number_of_exits)$. To obtain the static field, those (number_of_exits) matrices are put together by always taking the minimum value of the cells. The efficiency of our implementation is rather low. The computation of the static field matrix increases with $\mathcal{O}((I \cdot w)^3)$. However, we did not invest more time on enhancing it, because that is not the main part of our project.

5 Simulation Results and Discussion

5.1 Validation

A model validation would be done with measurement data of full scale tests. Since any full scale data is not available, validation is left open as a future step.

5.2 Post processing approach

The analysis was performed with 100 simulations per set of parameters. The mean values and standard deviations are plotted in the diagrams and listed in the tables. The terms *normal conditions* or *normal configurations* are used for simulations without additional obstacles in the cabin using the usual location of the emergency exits. An optimized version was simulated with a different placement of the exits. The number of exits remains the same. In a second approach, obstacles were implemented in the region of the middle exits. The time step is equal to the time each figure remains on the screen, while the simulation is plotted. The probability is explained in paragraph 4.3.4.

5.3 Simulation without obstacles around doors

Figures 11 and 12 on page 24 show the simulation domain without obstacles in normal and optimized configuration.

5.3.1 Simulation with different parameters under normal condition

Figure 13 on page 25 shows the different evacuation times by changing the number of passengers under normal condition. The parameters are the number of passengers per time step moving and their probability to do the best move. The more passengers are moving per time step the lower the evacuation time. With high probability of doing the best possible move, the standard deviation for each measurement decreases.

Plot 14 on page 25 shows the mean evacuation time versus the probability of each passenger doing the best possible move. As expected, the mean evacuation time, as well as the corresponding standard deviation is diametrically opposed to the probability.

5.3.2 Simulation with different parameters and optimized location of emergency exits

Figure 15 on page 26 illustrates the different evacuation times by changing the number of passengers using an optimized arrangement of exits. Again, the more passen-

Figure 11: Cabin without obstacles under normal configuration

Figure 12: Cabin without obstacles and with optimized exit location

gers moving per time step, the lower the evacuation time. With high probability of choosing the best possible move, the standard deviation for each measurement decreases. With optimized exit locations, the evacuation times are reduced by approx-

Figure 13: Mean evacuation time vs number of passengers moved per timestep

Figure 14: Mean evacuation time vs probability

imately 30 percent. In this case, the optimized exit locations are purely theoretical, because no stability aspects were taken into account.

Figure 16 on page 27 displays the mean evacuation time versus the probability of

each passenger selecting the best possible move. As expected, the mean evacuation time, as well as the corresponding standard deviation are decreasing with increasing probability. Here again the mean evacuation time was reduced by more than 30 percent.

Figure 15: Mean evacuation time vs number of passengers moved per timestep (optimized)

5.4 Simulation with obstacles around doors

Figures 17 and 18 on page 27 indicate both configurations of the simulation domains with obstacles. The obstacles are placed around the four middle doors and are colored grey. The obstacles act like walls. The static field has not been changed. The obstacles were moved to the new locations of the corresponding doors.

5.4.1 Simulation with different parameters and obstacles

Figure 19 on page 28 shows the different evacuation times by altering the number of passengers under normal condition. The parameters are the number of passengers per time step moving and their probability to perform the best move. The more passengers moving per time step, the lower the evacuation time. With high probability of choosing the best possible move, the standard deviation for each measurement decreases.

Plot 20 on page 29 shows the mean evacuation time versus the probability of each passenger to do the best possible move. Yet again, the mean evacuation time, as

Figure 16: Mean evacuation time vs probability (optimized)

Figure 17: Cabin with obstacles under normal configuration

well as the corresponding standard deviation are constantly declining, the higher the probability is set.

Exits with obstacles result in a longer period of evacuation. The difference to

Figure 18: Cabin with obstacles and optimized exit location

normal configuration is more than 60 per cent.

Figure 19: Mean evacuation time vs number of passengers moved per timestep (with obstacles)

Figure 20: Mean evacuation time vs probability (with obstacles)

5.4.2 Simulation with different parameters, optimized location of emergency exits and obstacles

Figure 21 on page 30 shows the different evacuation times with a modified number of passengers with an optimized arrangement of exits. The exits are not free of obstacles according to figure 18 on page 28. Again the more passengers are moving per time step, the lower the evacuation time. With increased probability of choosing the best possible move the standard deviation for each measurement decreases. With optimized exit locations, the evacuation times dropped by approximately 30 percent with respect to the normal exit configuration with obstacles. The evacuation time lasts about 40 per cent longer than the one without obstacles. In real life, this difference could be deadly, which indicates the major importance of free exits.

Figure 16 on page 27 shows the mean evacuation time versus the probability of each passenger to choose the best possible step. As eagerly awaited, the mean evacuation time, as well as the corresponding standard deviation are again diametrically opposed to the probability. In that particular case, the mean evacuation time plummeted over 30 per cent too.

Figure 21: Mean evacuation time vs number of passengers moved per timestep (optimized and with obstacles)

Figure 22: Mean evacuation time vs probability (optimized and with obstacles)

5.5 Discussion

The curves' level-off points in figure 23 and following, on pages 31 to 33, indicate a limit of passengers moving per time step. If more than 25 passengers move per time

step, the evacuation time remains reasonably steady. The reason of that behavior is due to reaching the maximum capability of the exits per time step. The same behavior is observed in the case with obstacles on figure 24 on page 32. The probability of choosing the correct move has a strong impact on the evacuation time. The higher the probability, the lower the evacuation time in both cases, with and without obstacles. The level-off trend in the high probability region exhibits the lower time rate. The results with obstacles look similar. Moreover the evacuation time increases with unexpected obstacles. "Unexpected" refers to the fact, that the static field has not been adapted. Agents follow their optimum path, until they see the unexpected obstacle. Then, they have to surround it. A considerably larger jamming trend can be observed around the exits concerned.

Figure 23: Mean evacuation time vs number of passengers moved per timestep

Figure 24: Mean evacuation time vs number of pax moved per timestep (with obstacles)

Figure 25: Mean evacuation time vs probability

Figure 26: Mean evacuation time vs probability (with obstacles)

6 Summary and Outlook

In this chapter, we will summarize the usability of the two models as well as the simulation results. So as to enhance our models we will propose some improvement suggestions.

6.1 Comparison

Model 1 persuaded with its simplicity. For instance, its simulation time, with only one motion per iteration, is quite as fast as the simulation time of Model 2 using more of which. Conversely, there is no way Model 1 can compete with Model 2 in terms of adaptability. Whereas in Model 2 one easily can alter the probabilities, as well as the number of agents moving per time step, in Model 1 one has to change the probability parameters in the corresponding .m-file. Let alone the fact that in Model 1 only one agent can move at a time. Having said that, the required RAM storage, in addition to the computing speed, are considered more positive using Model 1.

Conclusively, we decided to compute our simulations with Model 2, so there are no necessary changes to be done in the .m-files.

6.2 Simulation results

All in all, we concluded, that an alternative choice of exit locations could, at least theoretically, reduce the evacuation time to a third of its original time. Conversely, the alternative we suggested would lead the passengers to the wings, which is not exactly to be recommended due to explosion considerations.

Moreover, obstacles in the exit areas can extend the evacuation time up to 40 per cent which is extremely poor.

In addition, the number of agents moving per iteration is restricted. Using common sense, it is not hard to recognize, that a moving crowd consisting of 200 people causes a much higher chaos and jamming factor as a group of 10 people. According to our results, the best rate of agents moving per time step is reached at a number of 25 agents.

Finally, in all cases, a high probability augments the evacuation efficiency.

6.3 Outlook

In order to collect appropriate statements about the models' prospective, we summed up the difficulties occurred in the past to conclude possible developments of our consisting model.

Difficulties within the first model:

- Many assumptions had to be made to enable the simulation
- Only one movement per iteration \rightarrow slow simulation
- Complex description of the passenger's next step \rightarrow not general valid
- Probability must be changed in the .m file
- Exit locations must be changed in the .m file

Difficulties within the second model:

- Many assumptions had to be made to enable the simulation
- Long calculation time \rightarrow low numerical efficiency
- Many functions and files

Regarding the difficulties we experienced with our models, we can make following propositions to enhance them:

- Include a function to easily switch the exit locations
- Involve people with disabilities, children, and natural factors
- Enable interaction between the two decks
- Use calculated information for further analysis. For instance, if many people are in front of the nearest exit, choose the second nearest exit.
- Optimize visualization

There are several further proposals to upgrade our model. However, every enhancement is creating a more complex model and reduces its computational skills. All the assumptions we made (see page 8) could be eliminated or improved by other assumptions. Nevertheless, the model will get much more complicated and its efficiency questionable.
